Abstract. The disequilibrium between 210Po activity and 210Pb activity in seawater samples was determined along the GEOTRACES GA01 transect in the North Atlantic during the GEOVIDE cruise (May–June 2014). A steady-state model was used to quantify vertical export of particulate 210Po. Vertical advection was incorporated into one version of the model using time-averaged vertical velocity, which had substantial variance. This resulted in large uncertainties for the 210Po export flux in this model, suggesting that those calculations of 210Po export fluxes should be used with great care. Despite the large uncertainties, there is no question that the deficits of 210Po in the Iberian Basin and at the Greenland Shelf have been strongly affected by vertical advection. Using the export flux of 210Po and the particulate organic carbon (POC) to 210Po ratio of total (> 1 µm) particles, we determined the POC export fluxes along the transect. Both the magnitude and efficiency of the estimated POC export flux from the surface ocean varied spatially within our study region. Export fluxes of POC ranged from negligible to 10 mmol C m⁻² d⁻¹, with enhanced POC export in the Labrador Sea. The cruise track was characterized by overall low POC export relative to net primary production (export efficiency < 1 %–15 %), but relatively high export efficiencies were seen in the basins where diatoms dominated the phytoplankton community. The particularly low export efficiencies in the Iberian Basin, on the other hand, were explained by the dominance of smaller phytoplankton, such as cyanobacteria or coccolithophores. POC fluxes estimated from the 210Po/210Pb and 234Th/238U disequilibria agreed within a factor of 3 along the transect, with higher POC estimates generally derived from 234Th. The differences were attributed to integration timescales and the history of bloom events.

1 Introduction

The oceans play an essential role in the regulation of atmospheric CO₂ and the buffering of the global climate system (e.g., Sabine, 2004) by removing carbon from the atmosphere via dissolution and photosynthesis in the surface ocean, and storing it in the dissolved or particulate forms. An important component of this oceanic sequestration is the biological carbon pump, driven by sinking particles from the surface to the deep ocean (e.g., Falkowski et al., 1998; Ducklow et al., 2001).

The magnitude of particulate organic carbon (POC) export flux from the upper ocean was traditionally obtained...
from time-series sediment traps (e.g., Honjo et al., 2008) and the natural radiotracer pair, $^{234}\text{Th}/^{238}\text{U}$ (e.g., Bhat et al., 1968; Buesseler et al., 1992). Here we focus on the application of another natural radionuclide pair: polonium-210 ($^{210}\text{Po}$, $T_{1/2} = 138.4$ days) and its progenitor lead-210 ($^{210}\text{Pb}$, $T_{1/2} = 22.3$ years). The $^{210}\text{Po}/^{210}\text{Pb}$ pair has a different particle-binding dynamic compared to the $^{234}\text{Th}/^{238}\text{U}$ pair since both isotopes are particle reactive, whereas $^{238}\text{U}$ is conservative and remains dissolved in seawater (Djogic et al., 1986). However, the nature of the particle association differs between the isotopes. Lead-210 and $^{234}\text{Th}$ are only adsorbed to particle surfaces, whereas $^{210}\text{Po}$ is both adsorbed to surfaces and biologically reactive so it can be assimilated by organisms and even bioaccumulated (Fisher et al., 1983; Cherrier et al., 1995; Stewart and Fisher, 2003a, b). This behavior leads to a higher partitioning coefficient (relative association between the isotope and the particulate vs. the dissolved phase) of $^{210}\text{Po}$ compared to that of $^{210}\text{Pb}$ (e.g., Masqué et al., 2002; Wei et al., 2014; Tang et al., 2017).

Lead-210 in the water column comes both from atmospheric deposition and in situ production via the decay of $^{226}\text{Ra}$. The residence time of $^{210}\text{Pb}$ in the atmosphere is only of days to weeks (Moore et al., 1974; Turekian et al., 1977). Polonium-210 (produced by decay of $^{210}\text{Pb}$ via $^{210}\text{Bi}$ activity in aerosols, and the subsequent fluxes to the surface ocean, are only about 10%–20% of those of $^{210}\text{Pb}$ (Masqué et al., 2002). The large difference in their particle reactivity and half-lives often leads to a disequilibrium between $^{210}\text{Po}$ and $^{210}\text{Pb}$ activities in the upper water column as particles sink.

This deviation from secular equilibrium, often in the form of a deficit of $^{210}\text{Po}$ activity with respect to $^{210}\text{Pb}$ activity, can be used to estimate POC export in a similar manner to the application of the $^{234}\text{Th}/^{238}\text{U}$ disequilibrium (Friedrich and Rutgers van der Loeff, 2002; Verdeny et al., 2009; Wei et al., 2011). Particle export fluxes estimated from the $^{234}\text{Th}/^{238}\text{U}$ and the $^{210}\text{Po}/^{210}\text{Pb}$ disequilibria integrate export that has occurred on timescales of weeks to months prior to the sampling time, respectively. The use of both isotope pairs could provide complementary information on the causes, timing, and efficiency of export fluxes of POC (e.g., Murray et al., 2005; Stewart et al., 2007; Roca-Martí et al., 2016).

In this study along the GEOTRACES GA01 transect in the North Atlantic, we first used a traditional scavenging model with the assumptions of steady-state and negligible physical transport to derive $^{210}\text{Po}$ fluxes over different depths of the water column at 11 stations. Then, vertical advection (primarily upwelling) was considered, and its impact on $^{210}\text{Po}$ flux was assessed. Using the POC concentration, and particulate $^{210}\text{Po}$ activity in the particles collected by in situ pumps, sinking fluxes of POC were then calculated. The magnitude and efficiency of carbon export derived from the $^{210}\text{Po}/^{210}\text{Pb}$ disequilibrium was considered in relation to the composition of the phytoplankton community. Finally, the POC export fluxes estimated from $^{210}\text{Po}/^{210}\text{Pb}$ disequilibria were compared with those derived from $^{234}\text{Th}/^{238}\text{U}$ disequilibria.

2 Methods

2.1 Cruise track and hydrographic setting

The GEOVIDE cruise (GEOTRACES GA01 transect) was carried out in May–June 2014 from Lisbon to Newfoundland (Fig. 1). Seawater and particulate samples for $^{210}\text{Po}$ and $^{210}\text{Pb}$ activity analysis were collected from the water column at 11 stations (Fig. 1). The GA01 transect can be separated into five sections according to its biogeochemical characteristics, described in detail by Lemaître et al. (2018). From east to west, these are the Iberian Basin (stations 1, 13), the Western European Basin (stations 21, 26), the Iceland Basin (stations 32, 38), the Irminger Basin (stations 44, 60), and the Labrador Basin (stations 64, 69, 77).

2.2 Radionuclides sampling and analysis

Radionuclide data were produced by two collaborating laboratories to ensure higher counting statistics for $^{210}\text{Po}$ activity in the samples: the Laboratori de Radioactivitat Ambiental at Universitat Autònoma de Barcelona (UAB) (samples from stations 1, 13, and 21) and the Stewart Laboratory at Queens College (QC) (samples from stations 26, 32, 38, 44, 60, 69, and 77). The sampling method for total and particulate $^{210}\text{Po}$ and $^{210}\text{Pb}$ samples and the determination of the radionuclide activity was described in Tang et al. (2018). In brief, water samples (5–10 L each) for total $^{210}\text{Po}$ and $^{210}\text{Pb}$ activity
were collected using Niskin bottles at 10 full water column stations (16–22 depths/station) and at 1 station to 1000 m (9 depths), for a total of 200 samples. Particulate \(^{210}\)Po and \(^{210}\)Pb were collected at 3–10 depths per station between 15 and 800 m by using McLane in situ pumps equipped with a 53 µm PETEX screen to capture the large-size particles and a 1 µm quartz fiber QMA filter to capture small particles. The average equivalent volume filtered for particulate \(^{210}\)Po and \(^{210}\)Pb samples through the PETEX screen was 200 L and through the QMA filter was 70 L.

For water samples, Po and Pb isotopes (including the added chemical yield tracers of \(^{209}\)Po and stable lead) were co-precipitated with cobalt–ammonium pyrrolidine dithiocarbamate (Co-APDC) (Fleer and Bacon, 1984) at sea, but digested using concentrated HCl and HNO\(_3\) back at the home laboratories. Particulate samples were spiked with \(^{209}\)Po and stable lead before acid digestion (UAB: HNO\(_3\)/HCl/CF, QC: HNO\(_3\)/HCl). Polonium isotopes (\(^{209}\)Po and \(^{210}\)Po) were plated by deposition onto a sliver disc (Flynn, 1968) and their activity was determined by alpha spectrometry. After removing any remaining Po isotopes by running the plating solution through an anion exchange column, the solution was respiked with \(^{209}\)Po and stored for at least 6 months. Lead-210 activity was determined by plating the ingrowth of \(^{210}\)Po from \(^{210}\)Pb.

The activities of \(^{210}\)Po and \(^{210}\)Pb at the sampling date were determined by correcting for nuclide decay, ingrowth, chemical recoveries, detector backgrounds, and blank contamination (Rigaud et al., 2013).

### 2.3 The \(^{210}\)Po flux method

The export flux of \(^{210}\)Po was estimated from total \(^{210}\)Po and \(^{210}\)Pb activities using a one-box model (Broecker et al., 1973; Matsumoto, 1975; Savoye et al., 2006). The \(^{210}\)Po activity in the surface ocean is the result of a balance between atmospheric input, continuous production from the decay of \(^{210}\)Pb in seawater, radioactive decay of \(^{210}\)Po, removal onto sinking particles, and transport into or out of the box by advection and diffusion. Therefore, the general form of the mass balance equation for \(^{210}\)Po between sources and sinks is as follows:

\[
\frac{\partial \text{Po}}{\partial t} = F_{\text{Po}} + \lambda_{\text{Po}} I_{\text{Po}} - \lambda_{\text{Po}} I_{\text{Po}} - P + V,
\]

where \(\partial \text{Po}/\partial t\) is the change in \(^{210}\)Po activity with time, \(F_{\text{Po}}\) (dpm m\(^{-2}\) d\(^{-1}\)) is the atmospheric flux of \(^{210}\)Po to the sea surface, \(\lambda_{\text{Po}}\) is the decay constant of \(^{210}\)Po (0.005 d\(^{-1}\)), \(I_{\text{Po}}\) and \(I_{\text{Po}}\) (dpm m\(^{-2}\)) are the inventories of \(^{210}\)Pb and \(^{210}\)Po activities, \(P\) (dpm m\(^{-2}\) d\(^{-1}\)) is the removal flux of \(^{210}\)Po via sinking particles, and \(V\) (dpm m\(^{-2}\) d\(^{-1}\)) is the sum of the advective and diffusive fluxes.

The atmospheric flux of \(^{210}\)Po is usually ignored as it represents only \(\approx 2\%\) of the in situ production of \(^{210}\)Po from \(^{210}\)Pb in the upper water column of the open ocean (e.g., Cochran, 1992; Masqué et al., 2002; Murray et al., 2005; Verdeny et al., 2008). We first used a steady-state (SS) model that assumes the negligible atmospheric input of \(^{210}\)Po activity and ignores advection and diffusion. In this case, the \(^{210}\)Po flux \((P)\) can be simplified as follows:

\[
P = \lambda_{\text{Po}} (I_{\text{Po}} - I_{\text{Po}}).
\]

The influences of advection and non-steady-state (NSS) processes on the overall \(^{210}\)Po activity balance are discussed below in Sect. 4.1 and 4.2.

Many previous studies have used a single fixed integration depth for export calculations at all sampling locations (e.g., 100 m in the Antarctic Circumpolar Current, Rutgers van der Loeff et al., 1997; 120 m in the central equatorial Pacific, Murray et al., 2005). The GA01 transect, however, crossed diverse physical and biogeochemical conditions. Thus, investigating export at a single fixed depth for every station may bias the spatial comparisons of particle export. In this study, four site-specific integration depths were used for each station: the mixed-layer depth (MLD), the depth of the euphotic zone (Z\(_1\%\)), the primary production zone (PPZ), and the \(^{234}\)Th/\(^{238}\)U equilibrium depth (ThEq). The MLD was defined as a change in potential density of 0.03 kg m\(^{-3}\) relative to the potential density at 10 m (Weller and Plueddemann, 1996). Z\(_1\%\) was defined as the depth at which photosynthetic available radiation was 1% of its surface value (Jerlov, 1968). PPZ was the depth at which the fluorescence reaches 10% of its maximum (Owens et al., 2015). ThEq was the depth at the bottom of the total \(^{234}\)Th water column deficit, where the activity of \(^{234}\)Th equals that of \(^{238}\)U (data from Lemaître et al., 2018). These depths were used both to calculate \(^{210}\)Po and POC export and in order to compare the POC export fluxes estimated from the \(^{210}\)Po/\(^{210}\)Pb disequilibria to those derived from the \(^{234}\)Th/\(^{238}\)U disequilibria. Among the 11 stations, the depths of the MLD (23 ± 7 m) were similar to those at Z\(_1\%\) (31 ± 9 m), whereas the depths of the PPZ (72 ± 29 m) and ThEq (95 ± 43 m) were deeper and comparable to each other. For the depths of MLD, Z\(_1\%\), PPZ, and ThEq at which total radionuclides data are not available, the measured values of total \(^{210}\)Po and \(^{210}\)Pb activities were linearly interpolated (Table 1).

The \(^{210}\)Po flux was then used to derive the flux of POC by multiplying the deficit of \(^{210}\)Po by the ratio of POC concentration to \(^{210}\)Po activity (POC/\(^{210}\)Po) of the total and large particulate material. Particulate \(^{210}\)Po and POC data were not always available at the depths of the MLD, Z\(_1\%\), PPZ, and ThEq at our study sites. To estimate POC/\(^{210}\)Po ratios at these depths, a regression was performed between the measured POC/\(^{210}\)Po ratios and depth for each basin using a single power law function.

### 2.4 Quantification of the influence of the vertical advection on \(^{210}\)Po export

Cycloonic or anticyclonic eddies constantly impact the horizontal velocity fields at our study sites (Zunino et al., 2017), changing the current directions and making it difficult to es-
Table 1. The mixed-layer depth (MLD, defined as a change in potential density of 0.03 kg m\(^{-3}\) relative to the potential density at 10 m), the depth of the euphotic zone (\(Z_{1\%}\), defined as the depth at which photosynthetic available radiation was 1% of its surface value), the primary production zone (PPZ, at which the fluorescence reaches 10% of its maximum), and the \(234\text{Th} - 238\text{U}\) equilibrium depth (ThEq) at each station along the GA01 transect. Together with the 30-day (30 days prior to the sampling date) average vertical velocity within the 20 m under the corresponding depths (\(w_{20}\), 10\(^{-6}\) m s\(^{-1}\), downwards as positive direction). Primary production (PP) and net primary production (NPP) rates derived from 24 h bottle incubations (Fonseca-Batista et al., 2018; Lemaître et al., 2018) and from the VGPM products, respectively, are also presented. Note that the NPP rates were averaged for the previous 138 days (\(^{210}\text{Po}\) half-life) prior to the sampling date. Dates are in mm/dd/yy format.

</table>

To estimate the magnitude of horizontal velocities. This constant variability, together with the patchiness of sampling resolution, meant we could not assess the influence of horizontal advective processes on \(^{210}\text{Po}\) export estimates.

However, because we had relatively high depth resolution at each station, we did attempt to assess the influences of vertical advection on \(^{210}\text{Po}\) inventories at all the investigated depths by measuring the vertical gradient of \(^{210}\text{Po}\) activity and multiplying it by a time-averaged vertical velocity. Because the water column inventory of \(^{210}\text{Po}\) represents an integration of the changes over approximately the mean life of the isotope, we did not use the vertical velocity measured by the acoustic doppler current profiler (ADCP) at the sampling time, but a time-averaged vertical velocity from the Estimating the Circulation and Climate of the Ocean, Phase II (ECCO2). The activity gradient of \(^{210}\text{Po}\) below the depth \(z\) (i.e., the MLD, \(Z_{1\%}\), PPZ, and ThEq) at each station was calculated from the depth \(z\) (using the average activity in the layer of 0–\(z\) m) as starting point and \((A_{\text{Po}}^{z})\) and linearly interpolated through the measurements 20 m below \(z\) \((A_{\text{Po}}^{z+20})\) at each station. A positive gradient \((A_{\text{Po}}^{z+20} - A_{\text{Po}}^{z}) > 0\) was defined as higher activity at the depth of \((z + 20\) m) than the starting point. We labeled the vertical velocity \(w_{20}\), which was the 30-day (30 days prior to the sampling date) average vertical velocity between the depths of \(z\) and \((z + 20\) m). The flux of \(^{210}\text{Po}\) due to vertical advection \((F_{w})\) was calculated as the following:

\[
F_{w} = w_{20} \times (A_{\text{Po}}^{z+20} - A_{\text{Po}}^{z}).
\]
2.5 Satellite-based net primary production and phytoplankton composition

The 8-day net primary production (NPP) data with a spatial resolution of 0.083 by 0.083° were obtained from the Oregon State University Ocean Productivity standard products (http://www.science.oregonstate.edu/ocean.productivity/, last access: 18 January 2019), wherein NPP was estimated by the Vertically Generalized Production Model (VGPM) (Behrenfeld and Falkowski, 1997). Due to some missing data between November 2013 and February 2014, NPP for each station was averaged for the previous 138 days (210Po half-life) instead of 200 days (210Po mean life).

Monthly average concentrations of diatoms, coccolithophores, cyanobacteria, chlorophytes, and total chlorophyll with the spatial resolution of 0.67 × 1.25° were obtained from the Goddard Earth Science Data and Information Services Center Interactive Online Visualization and Analysis Infrastructure (Giovanni) (https://giovanni.gsfc.nasa.gov/giovanni/ last access: 18 January 2019, Acker and Lepouchk, 2007). Time-series (October 2013–July 2014, covering >200 days before sampling) data are averages over longitude for each month. We extracted data for the five basins individually and calculated the fraction of each phytoplankton group at each station as the ratio of their concentration to total chlorophyll concentration.

3 Results

3.1 Satellite-derived seasonal NPP and phytoplankton composition

The VGPM modeled NPP data along the GA01 transect was averaged over ~138 days prior to the sampling date (see Sect. 2.5, Table 1). Seasonal NPP at each station varied from low values of 44–79 to a maximum value of 109 mmol C m⁻² d⁻¹ at station 21. The Western European Basin had the highest seasonal NPP, followed by the Iberian Basin, while the Iceland Basin, the Irminger Basin, and the Labrador Basin all had similar NPP values in the range of 45–49 mmol C m⁻² d⁻¹. There was a shift in the biological community towards larger phytoplankton (e.g., diatoms) from east to west along the transect (Fig. 2). The basins for which diatoms were the dominant phytoplankton group did not necessarily have higher seasonal production relative to the basins where smaller phytoplankton (e.g., coccolithophores) were more abundant. Indeed, the Iberian Basin had the second highest seasonal NPP, despite the fact that the majority of chlorophyll was produced by coccolithophores. Despite the evidence that earlier blooms may have been driven by diatoms (see Sect. 4.2), these observations highlight the possible contribution of small particles to production, and possibly to export (proportional to their role in production according to Richardson and Jackson, 2007), along the transect. Moreover, this could also be due to shorter blooms in the Irminger and Labrador basins where the phytoplankton growth was light-limited during winter compared to the conditions in the Iberian and Western European basins.

The satellite-derived phytoplankton species composition demonstrated unique features within the basins (Fig. 2). The Iberian Basin was dominated (>60%) by coccolithophores between October 2013 and July 2014, but had a gradual increase in the contribution of diatoms until April 2014 and a decreasing contribution after that. In the Western European Basin, station 26 was dominated by diatoms all year round, while station 21 was dominated by diatoms, except in October 2013 and July 2014 when the combination of chlorophytes and coccolithophores contributed 35%–77% to the total chlorophyll concentration. The stations in the Iceland, Irminger, and Labrador basins were all dominated (>98%) by diatoms between October 2013 and July 2014.

3.2 One-month averaged vertical velocity $w_{20}$

The 1-month averaged vertical velocities $w_{20}$ ranged from $-36 \times 10^{-6}$ to $9 \times 10^{-6}$ m s⁻¹ along the transect (negative is upwelling, positive is downwelling, Table 1). The standard deviations of $w_{20}$ were generally of the same order as the values of $w_{20}$. Particularly large standard deviations, which exceed the typical values of the vertical velocity by a full order of magnitude, were found at stations 13 (35–55, 110–130 m) and 21 (110–130 m). These high standard deviations suggest that the data on $w_{20}$ should be used with great care. Downwelling was seen at stations 38, 44, 64, and 77 with the velocities in the range of $1 \times 10^{-6}$ to $9 \times 10^{-6}$ m s⁻¹.

Upwelling was seen at the remaining stations, with highest intensity at station 60 near Greenland (absolute value: 11–36 × 10⁻⁶ m s⁻¹). The upwelling velocities were roughly equivalent at stations 1, 13, 21, 26, 32, and 69 (absolute value: 1–5 × 10⁻⁶ m s⁻¹).

3.3 Total 210Po deficits

The vertical profiles of total 210Po and 210Pb activity at each station have been described in a companion article (Tang et al., 2018). Here we show the section view of the water column 210Po deficit (dpm 100 L⁻¹), which was calculated as total 210Pb activity minus total 210Po activity (Fig. 3). There were small 210Po deficits in the upper 100 m (including the majority of the depths of MLD, Z1%, PPZ, and ThEq at all stations) at stations 1, 13, and 21, whereas a relatively large excess of 210Po was observed at 100–400 m depth. Station 60 had the highest deficits of 210Po (~ 8 dpm 100 L⁻¹, n = 5) at 40–120 m depth. A large surface deficit of 210Po was found at station 64 (8 dpm 100 L⁻¹) and a surface excess was found at station 38 (~ 3.5 dpm 100 L⁻¹). There were positive 210Po deficits throughout most of the water column at stations in the Irminger and Labrador basins, whereas large 210Po excesses (negative deficits) below 100 m were generally seen in the
Iberian Basin and Western European basins. Such $^{210}$Po excess was likely related to the Iberian upwelling, which may have provided a source of $^{210}$Po activity.

### 3.4 The $^{210}$Po flux calculated from the deficit of $^{210}$Po alone

Using the data of total $^{210}$Po and $^{210}$Pb activities, the amount of $^{210}$Po escaping from the surface ocean via particles ($^{210}$Po fluxes, dpm m$^{-2}$ d$^{-1}$) was calculated using Eq. (2) assuming steady state and ignoring advection and diffusion (Table 2, $^{210}$Po/$^{210}$Pb term). The $^{210}$Po fluxes were negligible or very low at stations 1, 21, and 38. At the other stations the $^{210}$Po fluxes averaged $3.7 \pm 1.4, 4.6 \pm 2.6, 9.5 \pm 4.9$, and $14.4 \pm 12$ dpm m$^{-2}$ d$^{-1}$ at the MLD, $Z_{1\%}$, PPZ, and ThEq, respectively. The $^{210}$Po fluxes tended to increase with depth at 7 out of 11 stations (26, 38, 44, 60, 64, 69, and 77). At the MLD, $Z_{1\%}$ and PPZ, the largest $^{210}$Po fluxes were all found in the Labrador Basin. The other four basins had relatively similar $^{210}$Po export fluxes (2.1–2.8 dpm m$^{-2}$ d$^{-1}$) at the MLD and $Z_{1\%}$. The West European Basin had much higher $^{210}$Po flux (8.7 dpm m$^{-2}$ d$^{-1}$) relative to that in the Iberian Basin (−0.1 dpm m$^{-2}$ d$^{-1}$) at the PPZ. At the ThEq,
Table 2. The total $^{210}$Po flux as the sum of the flux calculated from the deficit and vertical advection, together with POC/$^{210}$Po ratios in particles > 1 μm (derived from the power law function in Fig. 5) and POC fluxes derived from $^{210}$Po at the corresponding depths. The uncertainties of $^{210}$Po export flux are associated with the activity uncertainty of the radionuclides. The error for the calculated particulate POC/$^{210}$Po ratio in each basin is the standard error of regression. The uncertainties of the $^{210}$Po-derived POC flux were estimated based on the propagation of error.

on the other hand, the Irminger Sea had the highest $^{210}$Po fluxes followed by the West European Basin. The lowest $^{210}$Po fluxes at all investigated depths were generally found in the Iberian Basin.

### 3.5 POC/$^{210}$Po ratios in particles

Most of the ratios of POC concentration to $^{210}$Po activity ($\text{µmol dpm}^{-1}$) in the large-size fraction of particles ($\text{POC}/^{210}\text{Po}_{\text{LSF}}, > 53 \text{ µm}$) were comparable to or higher than those in the small-size fraction ($\text{POC}/^{210}\text{Po}_{\text{SSF}}, 1–53 \text{ µm}$), although a few samples at stations 13, 26, 44, 64, and 77 had lower values of $\text{POC}/^{210}\text{Po}_{\text{LSF}}$ than those of $\text{POC}/^{210}\text{Po}_{\text{SSF}}$ (Table 3, Fig. 4a). The POC/$^{210}$Po ratio in the total particles ($> 1 \text{ µm}$, the combination of small and large particles, $\text{POC}/^{210}\text{Po}_{\text{TPF}}$) was similar to that in the small particles (SSF), within about 97% (Table 3, Fig. 4b). This is because over 80% of the particulate $^{210}$Po activity was associated with the small-size fraction (Tang et al., 2018) likely due to the large surface area of abundant small particles. Because of the possible link between small particles and export along the transect discussed in Sect. 3.1, and the results that scavenging of $^{210}$Po was governed by the small particles (Tang et al., 2018), we propose to use this total particulate fraction in addition to the more commonly used large-size fraction to calculate POC export along this cruise track.

The POC/$^{210}$Po in total particles ($\text{POC}/^{210}\text{Po}_{\text{TPF}}$) varied from 19 to 1300 $\text{µmol dpm}^{-1}$ with a mean of 290 ± 320 $\text{µmol dpm}^{-1}$ ($n = 51$, upper 800 m). The variability of $\text{POC}/^{210}\text{Po}_{\text{TPF}}$ ratios in this study is in line with previous observations in the Antarctic Circumpolar Current (300–1200 $\text{µmol dpm}^{-1}$ for particles $> 1 \text{ µm}$) (Friedrich and Rutgers van der Loeff, 2002) and the central Arctic (90–1900 $\text{µmol dpm}^{-1}$ for particles $> 53 \text{ µm}$) (Roca-Martí et al., 2016). The average ratio of 290 $\text{µmol dpm}^{-1}$ is comparable to those observed in the central equatorial Pacific (202 ± 90 $\text{µmol dpm}^{-1}$ for particles $> 0.45 \text{ µm}$) (Murray et al., 2005), the North Atlantic (290 ± 70 $\text{µmol dpm}^{-1}$ for particles $> 1 \text{ µm}$) (Rigaud et al., 2015), and the South Atlantic (113 ± 80 $\text{µmol dpm}^{-1}$ for particles $> 0.7 \text{ µm}$) (Sarin et al., 1999).

The measured POC/$^{210}$Po ratios in total particles at each station and depth were grouped into the five basins and fitted against depth using a single power law function in each basin (Fig. 5). The fit equations were used to calculate total particulate POC/$^{210}$Po ratios at the investigated depths at each station (Table 3).

### 4 Discussion

#### 4.1 Physical advection effects on $^{210}$Po export fluxes

In the study region, there were consistent patterns of circulation traveling through and near our sampling sites during the GEOVIDE cruise. From east to west the cruise track crossed...

</table>
the North Atlantic Current, the East Reykjanes Ridge Current, the Irminger Current, the Irminger Gyre, the eastern and western boundary currents and the Labrador Current (Fig. 1 in García-Ibáñez et al., 2018). Additionally, short-lived eddies and fronts were also observed during the cruise, particularly in the OVIDE section from Portugal to Greenland (García-Ibáñez et al., 2018; Zunino et al., 2017). In this dynamic region advective influences may be important to include in calculations of $^{210}$Po export. Despite this knowledge, we could not include horizontal advection in our model because the horizontal resolution of our sample sites was not sufficient to constrain reliable horizontal gradients of $^{210}$Po activity in the study region. This assumption of negligible horizontal physical transport has been made in most $^{210}$Po studies because of a similar lack of spatial resolution (e.g., Kim and Church, 2001; Stewart et al., 2010; Rigaud et al., 2015), and may be justified in some open-ocean settings where horizontal gradients in $^{210}$Po activity are small (e.g., Wei et al., 2011). For more dynamic regimes, such as along the GA01 transect, however, this assumption needs to be carefully evaluated, and the relative importance of advective $^{210}$Po flux should be assessed if possible.

We did, however, have enough sampling depths at each station to assess the vertical variability in $^{210}$Po activity and to estimate the impact of vertical advection on the $^{210}$Po flux. The range of $^{210}$Po activity flux due to vertical advection ($-40$ to $14$ dpm m$^{-2}$ d$^{-1}$, Table 2) was of the same magnitude as the steady-state fluxes calculated from the deficit alone ($-5$ to $37$ dpm m$^{-2}$ d$^{-1}$, Table 2). The magnitude of the uncertainty of the $^{210}$Po export flux due to vertical advection was influenced by the large variance in vertical velocity field mentioned in Sect. 3.2. When excluding the three depths at stations 13 and 21, where the monthly vertical velocity average had substantial standard deviations (an order of magnitude greater than $u_{203}$), the uncertainty of the $^{210}$Po export flux was on average 2-fold larger than the calculated $^{210}$Po export flux. The largest positive vertical advective $^{210}$Po fluxes were at station 1, where the Iberian upwelling increased the calculated flux by 150 %–500 %.

The largest negative vertical advective $^{210}$Po fluxes were seen at station 60 where upwelling decreased the $^{210}$Po flux by 370 %–1100 % at the depths of the MLD, $Z_{1 \%}$, and PPZ. This is because the upwelling velocity was high at those depths ($14-36 \times 10^{-6}$ m s$^{-1}$, Table 1) and the upwelled water was depleted in $^{210}$Po activity. The vertical advective transport was smaller at the MLD and $Z_{1 \%}$ at station 13, at the ThEq at station 21, and at the PPZ and ThEq at station 64, with contributions lower than 6 % of the total $^{210}$Po fluxes. Including vertical advection in our flux estimates at all other depths, however, increased or decreased the $^{210}$Po fluxes by 10 %–180 %. Like with vertical advection, neglecting horizontal advection can result in either an underestimate or overestimate of $^{210}$Po export flux depending on whether the advected water is enriched or depleted in $^{210}$Po. However, because our study region was characterized by distinct water masses separated over tens to hundreds of meters in the vertical plane, whereas those same water masses covered huge distances (hundreds to thousands of kilometers) in the horizontal plane (Fig. 4 in García-Ibáñez et al., 2018), vertical advection would most likely result in more change in physical and chemical parameters over the scale of sampling than horizontal advection would. Because the advective $^{210}$Po export flux was calculated as the product of the velocity of the water mass and the gradient of $^{210}$Po activity in the corresponding direction, horizontal advection would most likely contribute a much smaller range of advective $^{210}$Po flux estimates.

Overall, the influence of physical advection on $^{210}$Po activity may range from relatively unimportant to dominant depending on the study area. In this study, we observed physical processes influencing $^{210}$Po fluxes, in particular at stations 1 and 60. For future studies of $^{210}$Po and $^{210}$Pb activity in regions of established upwelling or ocean margins, we suggest designing the sampling plan so that the magnitude and variability of these processes may be incorporated into $^{210}$Po export models. At ocean margins, in particular, more water samples should be taken to improve the resolution of horizontal features.

### 4.2 Non-steady-state effects on $^{210}$Po export fluxes

To our knowledge, three time-series studies of $^{210}$Po and $^{210}$Pb activities have been conducted to date and have as-

---

**Figure 4.** Plots of the ratios of POC concentration to $^{210}$Po activity in (a) the large (>53 µm) particles (POC/$^{210}$Po_LSF) against the small (1–53 µm) particles (POC/$^{210}$Po_SSF), and in (b) the total (>1 µm) particles (POC/$^{210}$Po_TPF) against the small particles. The black lines indicate the 1 : 1 line.
Figure 5. The ratios of POC concentration to \(^{210}\text{Po}\) activity in the total particles vs. depth in each basin along the GA01 transect. Power law regression (red line) was fitted for POC/\(^{210}\text{Po}\) against depth in each plot: the Iberian Basin (stations 1, 13), West European Basin (stations 21, 26), Iceland Basin (stations 32, 38), Irminger Basin (stations 44, 60), and Labrador Basin (stations 64, 69, 77). The data points denoted as filled by black circles were outliers (points at a distance greater than 1.5 standard deviations from the power law model) and excluded from the power law regression.

Atmospheric aerosol deposition along the GA01 transect was reportedly low without the significant influence of the Saharan plume (Shelley et al., 2017). However, it is important to assess the \(\partial\text{Po}/\partial t\) term that was associated with the site-specific bloom events during the cruise. Satellite estimates of net primary production (VGPMP model) for the eight 8-day periods prior to the sampling date (∼2 months) were calculated at each station (Fig. 6). Two months of NPP data are needed because such a timescale could ensure the sensitivity for NSS estimates (Friedrich and Rutgers van der Loeff, 2002; Stewart et al., 2007). NPP values for the 2-month period were in the ranges of 51–184, 39–403, 22–131, 18–204, 16–210 mmol C m\(^{-2}\) d\(^{-1}\) in the Iberian Basin, the West European Basin, the Iceland Basin, the Irminger Basin, and the Labrador Basin, respectively, indicating the occurrence of blooms during this time period along the transect that might have influenced the \(^{210}\text{Po}\) fluxes derived from Eq. (1).

SS may have underestimated the \(^{210}\text{Po}\) export along the GA01 transect depending on the stage of the bloom before sampling. For example, at station 21 the largest NPP peak (403 mmol C m\(^{-2}\) d\(^{-1}\)) occurred 2 weeks before our sampling date and diminished rapidly (∼100 mmol C m\(^{-2}\) d\(^{-1}\) at sampling time). The combination of high phytoplankton export and a sudden decrease in NPP may have significantly lowered the \(^{210}\text{Po}\) activity in the upper waters, resulting in a negative \(\partial\text{Po}/\partial t\), and thus the SS model may have underestimated the true \(^{210}\text{Po}\) flux. Temporal variations were also seen in the time-series phytoplankton community composition, in particular at stations 1 and 13 (Fig. 2). Both stations were dominated (>60 %) by coccolithophores between October 2013 and July 2014, but appeared to have a diatom bloom in April 2014 before sampling. Polonium-210 and \(^{210}\text{Pb}\) tend to bind to specific biopolymeric functional groups, leading to fractionation during their sorption onto particles (Quigley et
al., 2002; Chuang et al., 2013; Yang et al., 2013). The temporal variation of phytoplankton composition could therefore also lead to non-steady-state effects on the overall $^{210}$Po activity balance, which are difficult to assess but deserve more attention.

The NSS effect on the $^{234}$Th fluxes at the ThEq were evaluated during the same cruise along the GA01 transect in Lemaitre et al. (2018) by using the NSS model developed in Savoye et al. (2006). Because the cruise plan did not allow an opportunity to reoccupy the study areas over time, the authors made the assumption that $^{234}$Th activity was in equilibrium with $^{238}$U activity at the starting date of the bloom. Their results suggested that the NSS $^{234}$Th fluxes were about 1.1 to 1.3 times higher than the SS estimates in the Iberian and West European basins, and 1.4 to 2.1 times higher in the Iceland, Irminger, and the Labrador basins. We did not attempt to apply the same technique to estimate NSS $^{210}$Po fluxes in this study because the assumption of equilibrium between $^{210}$Po activity and $^{210}$Pb activity at the starting date of the bloom may be inappropriate and the $^{210}$Po deficit integrates over a longer time period (months) than a typical bloom event (days to weeks).

### 4.3 POC flux calculated from $^{210}$Po flux

The POC export fluxes were calculated by multiplying both the $^{210}$Po export fluxes calculated from the deficit alone (SS without advection) and the total $^{210}$Po fluxes (sum of the fluxes calculated from the $^{210}$Po deficit and vertical advection) by the total particulate (> 1 µm) POC/$^{210}$Po ratios at the corresponding depths (Table 2, Fig. 7). The POC fluxes calculated from only the deficit term and the total term ranged from negligible to 7 mmol C m$^{-2}$ d$^{-1}$ and from negative to 10 mmol C m$^{-2}$ d$^{-1}$, respectively. This is in good agreement with the SS fluxes derived via the $^{210}$Po/$^{210}$Pb method ignoring advection in other regions of the world ocean (negligible to 8.5 mmol C m$^{-2}$ d$^{-1}$) (e.g., Shimmield et al., 1995; Sarin et al., 1999; Kim and Church, 2001; Stewart et al., 2007; Verdeny et al., 2008; Roca-Martí et al., 2016; Subha Anand et al., 2017).

The highest-estimated POC fluxes (Table 2) along the transect were observed at most of the investigated depths in the Labrador Sea and at the Greenland Shelf, whereas the lowest export was in the Iberian and West European basins. An exception to this pattern was found at station 26, where POC
POC fluxes derived from $^{210}$Po for the mixed-layer depth (MLD), the base of the euphotic zone ($Z_{1\%}$), the base of the primary production zone (PPZ), and the $^{234}$Th/$^{238}$U equilibrium depth (ThEq). (a) POC fluxes derived from the $^{210}$Po fluxes that were calculated from the deficit alone; (b) POC fluxes derived from the sum of the $^{210}$Po fluxes that were calculated from the $^{210}$Po deficit and vertical advective flux. Note that the $> 1 \mu$m particles were used to calculate the POC/$^{210}$Po ratios. The stations were plotted from west to east.

The negligible deficit of $^{210}$Po at the MLD and $Z_{1\%}$ seen at stations 21, 38 and 44 leads to negligible $^{210}$Po-derived POC fluxes at those depths and stations (Table 2, Fig. 7). The relatively low POC export (negligible $-1.7 \text{ mmol C m}^{-2} \text{ d}^{-1}$) at stations 1 and 13, on the other hand, resulted from low particulate POC/$^{210}$Po ratios (Table 2). In fact, the Iberian Basin had the lowest measurements of particulate POC/$^{210}$Po ratios in both the small- and large-size fractions relative to the other four basins along the transect (Fig. 4). This basin was also the only region along the transect where the phytoplankton community was not dominated by diatoms but by smaller phytoplankton, in particular coccolithophores. Smaller phytoplankton cells could scavenge more $^{210}$Po (higher particulate $^{210}$Po activity relative to the large particles) due to larger surface area per unit of volume, lowering their ratio of POC concentration to $^{210}$Po activity.

4.4 POC export efficiency

The POC export flux calculated from the total $^{210}$Po at the depth of the PPZ was compared to the satellite-derived NPP over ~138 days (see Sect. 2.5) at each station, and the ratio was reported as the POC export efficiency. The export efficiencies in this study were below 10% at 10 out of 11 stations, averaging $6 \pm 4\%$ ($n=10$, excluding the negative value at station 60, Fig. 8). Export efficiencies <10% observed here were similar to those found in the equatorial Pacific, the Arabian Sea, and at the BATS site (Buesseler, 1998; Subha Anand et al., 2017), but lower than those reported at high-latitude sites (>25%), such as the Arctic (Gustafsson and Andersson, 2012; Moran et al., 1997; Roca-Martí et al., 2016), the Bellingshausen Sea (Shimmield et al., 1995), and the Antarctic Polar Front (Rutgers van der Loeff et al., 1997).
Export efficiencies ranged from 0.5% to 2.5% in the Iberian Basin, while the values in the Irminger Basin (3±3%, excluding station 60) were similar to the export efficiencies in the Western European Basin (5±5%) and in the Iceland Basin (6±6%). The export efficiencies, in contrast, were larger in the Labrador Basin (10±3%). The lowest export efficiencies observed in the Iberian Basin were consistent with the dominance of smaller phytoplankton species (e.g., coccolithophores and cyanobacteria; Fig. 2). Indeed, small cells are usually slow-sinking particles that are likely more prone to degradation (Villa-Alfageme et al., 2016), leading to lower export efficiencies. Conversely, the higher export efficiencies at other stations, all generally dominated by diatoms (Fig. 2), support the idea that diatoms may be more efficient in exporting POC than smaller phytoplankton (Buesseler, 1998). Differences in export efficiencies between the basins dominated by diatoms suggest that other factors may also play some role (e.g., temporal decoupling between production and export).

The POC export efficiency could also vary widely within the same basin. Taking the two stations in the Western European Basin for instance, export efficiency at station 26 was ~5-fold greater than that estimated at station 21, likely consistent with a lower contribution of diatoms and a higher contribution of smaller phytoplankton at station 21 relative to those at station 26 (Fig. 2). But overall the time-series composition of the phytoplankton community at the two stations was similar (Fig. 2). The site-specific environment may have impacted the export of the same cell type to different degrees (Durkin et al., 2016). Station 26 was in the middle of the SAF, and the mesoscale physical processes (i.e., turbulence and mixing) at the front can introduce nutrients into the local euphotic zone (Lévy et al., 2012). Large phytoplankton species generally dominate in these nutrients-rich waters and can promote massive episodic particle export (e.g., Kemp et al., 2006; Guidi et al., 2007; Waite et al., 2016).

4.5 Comparison of 210Po and 234Th derived POC fluxes

The measurements of 234Th/238U disequilibrium to estimate POC export flux were simultaneously carried out during the GEOVIDE cruise (Lemaître et al., 2018). The authors discussed the influence of vertical advection on 234Th export flux and concluded it can be neglected. In the present study, estimates of 234Th-derived POC (234Th-POC) flux were compared to 210Po-derived POC (210Po-POC) flux. To avoid discrepancies, both the 234Th-POC and 210Po-POC flux estimates were calculated at the depth of ThEq using the POC/radionuclide ratio in total particles >1 µm (TPF) and large particles >53 µm (LSF), and both methods ignored physical transport and assumed steady state, where any deviation from secular equilibrium was created by sinking particles with an adsorbed and/or absorbed excess of the short-lived daughter isotope.

4.5.1 210Po flux vs. 234Th flux

The integrated 210Po and 234Th fluxes at the depth of ThEq were compared (Fig. 9). There was a spatial trend of 234Th flux, but not 210Po flux along the transect; 234Th fluxes at stations 1 to 38 (eastern section, 1580±430 dpm m⁻² d⁻¹) were significantly greater (Wilcoxon rank sum test, p value <0.002) than the fluxes at stations 44 to 77 (western section, 710±230 dpm m⁻² d⁻¹). The means of the 210Po fluxes in the western and eastern sections were not statistically different from each other (Wilcoxon rank sum test, p value = 0.3). However, the flux of 210Po and 234Th correlated with each other better in the western (n = 5, R² = 0.6) than in the eastern (n = 6, R² = 0.01) sections.

These relationships may be related to both the stage of the bloom and different half-lives of the two isotopes. Indeed, 234Th fluxes integrate the conditions that occurred days to weeks prior to the sampling date, while the 210Po method integrates the flux over the past few months. Within the Iberian Basin, stations 1 and 13 were sampled weeks to months after the bloom development (Fig. 6). The moderate to relatively high 234Th fluxes are thus surprising. Lemaître et al. (2018) argue that the greater fluxes there might be related to the proximity of the Iberian margin, where particle dynamics were intense and lithogenic particles were numerous (Gourain et al., 2018). A temporal decoupling between production and export could be an alternative possibility. The Western European and Icelandic basins were sampled during bloom development, and the NPP peaks occurring just before sampling may have promoted the high fluxes. In fact, these basins have been characterized by the presence of fast-sinking particles during the bloom (Villa-Alfageme et al., 2016), likely also explaining the high export. In contrast, the lower export observed in the western section may be due to...
Hayes et al., 2018). Indeed, the changes in the water column (Verdeny et al., 2009; Shimmield et al., 1995; Stewart et al., 2007; Verdeny et al., 2018; LSF) were examined and used to calculate POC export flux. The POC/210Po and POC/234Th ratios in the particles at the depths of ThEq were derived from the power law functions in each basin (TPF POC/210Po in Table 2, LSF POC/234Th in Lemaitre et al., 2018; LSF POC/210Po and TPF POC/234Th not shown). The TPF POC/210Po and TPF POC/234Th ratios had very similar spatial trends (n = 11, R² = 0.8, p value < 0.0001) along the transect, with the lowest POC/radionuclide ratios in the Iberian and Western European basins and the highest ratios in the Labrador Sea. In contrast, the LSF POC/210Po ratios were not correlated with LSF POC/234Th ratios (n = 11, R² = 0.3, p value = 0.07). The correlation of values within the TPF but not the LSF suggests that the composition of large particles was different from that of the total particles, and that the difference in particle association between POC and 210Po and 234Th was greater in large particles than in total particles.

4.5.3 210Po-derived POC vs. 234Th-derived POC

When the radionuclide fluxes were multiplied by the POC/radionuclide values, the range of the calculated POC fluxes were negligible to 7 mmol C m⁻² d⁻¹ and negligible to 12 mmol C m⁻² d⁻¹ via the 210Po method using the TPF and LSF POC/210Po ratios, respectively, and from 2.5 to 13 mmol C m⁻² d⁻¹ and from 1 to 12 mmol C m⁻² d⁻¹ via the 234Th method using the TPF and LSF POC/234Th ratios (Fig. 10). The 234Th-POC and 210Po–POC fluxes agreed within a factor of 3 along the transect, with higher POC estimates derived from the 234Th method in 9 out of 11 stations. This was consistent with previous studies that have typically found higher-estimated POC flux via the 234Th method (e.g., Shimmield et al., 1995; Stewart et al., 2007; Verdeny et al., 2009).

When using the total particle POC/radionuclide ratios, only stations 26 and 60 were characterized by slightly higher 210Po-derived POC flux estimates than 234Th-derived estimates (0.2 and 1.5-fold, respectively). In contrast, at station 1 the difference between the methods was greatest, with the 210Po-derived POC flux negligible and the 234Th-POC flux of about 7 mmol C m⁻² d⁻¹. At stations 13, 21, and 44, the 234Th-POC fluxes were greater than 210Po–POC estimates by almost 1-fold, whereas in the Iceland and Labrador basins, the 234Th-POC fluxes were larger than 210Po–POC estimates by 3- and 2-fold, respectively. When using the large particle POC/radionuclide ratios, only in the Irminger Basin was there higher 210Po-derived POC flux than 234Th-derived POC flux (>0.2 to 3-fold). In the Iberian Basin, the greatest difference between the methods was found at station 1, where 210Po-derived POC flux was negligible, while 234Th-derived POC flux was the highest along the transect but with a large

![Figure 10. Plot of the POC flux derived from 210Po (210Po–POC) versus the POC flux derived from 234Th (234Th-POC) at 11 stations along the GA01 transect. Both the fluxes of 210Po and 234Th were calculated from the deficit term alone, assuming steady state and negligible physical transport. The POC/radionuclide ratios on (a) total particulate fraction (TPF, > 1 µm) and (b) large-size fraction (LSF, > 53 µm) were used to calculate the POC flux. The fluxes were integrated down to the depth at which the 234Th activity returned to equilibrium with 238U activity (ThEq). The numbers in the plot are station numbers. The colored dots of the stations correspond to the basins.](www.biogeosciences.net/16/309/2019/biogeosciences-16-309-2019.png)

4.5.2 POC/210Po vs. POC/234Th ratio

In order to calculate POC export flux, one needs both the export of the daughter nuclide at a defined depth as well as the particulate POC/radionuclide ratio on the sinking particles. In situ pump filtered particles, either operationally defined as small (1–53 µm, SSF), large (>53 µm, LSF), or total (>1 µm, TPF) particles, may all represent a combination of sinking and non-sinking particles. In the present study, the particulate POC/radionuclide ratio on the TPF and LSF were examined and used to calculate POC export flux. The POC/210Po and POC/234Th ratios in the particles at the depths of ThEq were derived from the power law functions in each basin (TPF POC/210Po in Table 2, LSF POC/234Th in Lemaitre et al., 2018; LSF POC/210Po and TPF POC/234Th not shown). The TPF POC/210Po and TPF POC/234Th ratios had very similar spatial trends (n = 11, R² = 0.8, p value < 0.0001) along the transect, with the lowest POC/radionuclide ratios in the Iberian and Western European basins and the highest ratios in the Labrador Sea. In contrast, the LSF POC/210Po ratios were not correlated with LSF POC/234Th ratios (n = 11, R² = 0.3, p value = 0.07). The correlation of values within the TPF but not the LSF suggests that the composition of large particles was different from that of the total particles, and that the difference in particle association between POC and 210Po and 234Th was greater in large particles than in total particles.

4.5.3 210Po-derived POC vs. 234Th-derived POC

When the radionuclide fluxes were multiplied by the POC/radionuclide values, the range of the calculated POC fluxes were negligible to 7 mmol C m⁻² d⁻¹ and negligible to 12 mmol C m⁻² d⁻¹ via the 210Po method using the TPF and LSF POC/210Po ratios, respectively, and from 2.5 to 13 mmol C m⁻² d⁻¹ and from 1 to 12 mmol C m⁻² d⁻¹ via the 234Th method using the TPF and LSF POC/234Th ratios (Fig. 10). The 234Th-POC and 210Po–POC fluxes agreed within a factor of 3 along the transect, with higher POC estimates derived from the 234Th method in 9 out of 11 stations. This was consistent with previous studies that have typically found higher-estimated POC flux via the 234Th method (e.g., Shimmield et al., 1995; Stewart et al., 2007; Verdeny et al., 2009).

When using the total particle POC/radionuclide ratios, only stations 26 and 60 were characterized by slightly higher 210Po-derived POC flux estimates than 234Th-derived estimates (0.2 and 1.5-fold, respectively). In contrast, at station 1 the difference between the methods was greatest, with the 210Po-derived POC flux negligible and the 234Th-POC flux of about 7 mmol C m⁻² d⁻¹. At stations 13, 21, and 44, the 234Th-POC fluxes were greater than 210Po–POC estimates by almost 1-fold, whereas in the Iceland and Labrador basins, the 234Th-POC fluxes were larger than 210Po–POC estimates by 3- and 2-fold, respectively. When using the large particle POC/radionuclide ratios, only in the Irminger Basin was there higher 210Po-derived POC flux than 234Th-derived POC flux (>0.2 to 3-fold). In the Iberian Basin, the greatest difference between the methods was found at station 1, where 210Po-derived POC flux was negligible, while 234Th-derived POC flux was the highest along the transect but with a large
uncertainty (12 ± 22 mmol C m−2 d−1), and at station 13 the 234Th-POC flux was greater than the 210Po–POC estimate by 4-fold. In the Western European, Iceland, and Labrador basins, the 234Th-POC fluxes were larger than 210Po–POC estimates by 5, 4, and 2-fold.

Wilcoxon rank sum tests revealed that the 234Th-POC estimates were significantly greater than 210Po-derived POC export at the stations from the Iberian Basin to the Iceland Basin (n = 6, TPF: p value < 0.01, LSF: p value < 0.02), but not at the stations from the Irminger Basin to the Labrador Basin (n = 5, TPF: p value > 0.1, LSF: p value = 1). Since the ratios of POC to radionuclides for total particles had very similar spatial trends along the transect, the discrepancy between TPF 234Th-POC and TPF 210Po–POC flux estimates must be driven primarily by the discrepancy between the SS estimates of 234Th and 210Po fluxes, discussed in Sect. 4.5.1. In contrast, the discrepancy between the POC to isotope ratios in the large particle may have led to some degree of discrepancy between the LSF 234Th-POC and LSF 210Po–POC flux estimates.

5 Conclusions

This study used the water column 210Po and 210Pb activity data to constrain the 210Po particulate flux from the mixed-layer depth, the base of the euphotic zone and primary production zone, and the 234Th–238U equilibrium depth. The ratios of POC concentration to 210Po activity on the total particulate (> 1 µm) fraction and large particulate fraction (> 53 µm) were used to estimate POC export fluxes. We have been able to include vertical advection into a steady-state model to calculate the 210Po flux along the transect. The scale of 210Po fluxes due to vertical advection was of the same magnitude as the steady-state fluxes calculated from the 210Po deficit alone. The 210Po-derived POC export fluxes varied spatially, ranging from negligible to 10 mmol C m−2 d−1 along the transect, with the highest export fluxes in the Labrador Sea. POC export efficiencies (flux relative to production) also showed regional differences, ranging from negligible to 13 % along the transect. Higher export efficiencies were seen in the basins where diatoms dominated the phytoplankton community. The low-export efficiencies recorded in the Iberian Basin, on the other hand, may be associated with the dominance of smaller phytoplankton, such as coccolithophores. POC export fluxes estimated from the water column 210Po/210Pb and 234Th/238U disequilibria agreed within a factor of 3 across our study region, with higher POC estimates generally derived from the 234Th method. The differences were attributed to integration timescales and the history of bloom events.

Data availability. The total and particulate 210Po and 210Pb activity data from the GEOVIDE cruise can be found in the companion article (Table S2 in Tang et al., 2018).

Competing interests. The authors declare that they have no conflict of interest.

Special issue statement. This article is part of the special issue “GEOVIDE, an international GEOTRACES study along the OVIDE section in the North Atlantic and in the Labrador Sea (GA01)”. It is not associated with a conference.

Acknowledgements. We thank the captain (Gilles Ferrand) and crew of the R/V Pourquoi Pas? and the chief scientists (Géraldine Sarthou and Pascale Lherminier) of the GEOVIDE cruise. We also thank Pierre Branellec, Floriane Desprez de Géscin-court, Michel Hamon, Catherine Kermabon, Philippe Le Bot, Stéphane Leizour, Olivier Ménage, Fabien Pérault, and Emmanuel de Saint-Léger for their technical support during the GEOVIDE expedition; Catherine Schmechigt for the GEOVIDE database management, and Phoebe Lam for providing two modified McLane in situ pumps; Frédéric Plançon, Virginie Sanial, and Catherine Jeandel for their assistance with pump deployments and particulate sample collection. The authors also thank Arnout Roukaerts, Debany Fonseca-Batista, Florian Deman, and Frank Dehairs for providing primary production data. Funding for the GEOVIDE cruise was provided by the French National Research Agency (ANR-13-BS06-0014, ANR-12-PDOC-0025-01), the French National Center for Scientific Research (CNRS-LEFE-CYBER), the LabexMER (anr-10-LABX-19), and Ifremer. Gillian Stewart and Yi Tang were supported by NSF award #OCE 1237108. The Generalitat de Catalunya also helped through its grant 2017 SGR-1588. This work is contributing to the ICTA “Unit of Excellence” (MinECo, MDM2015-0552). Maxi Castrillejo and Montserrat Roca-Martí were funded by an FPU PhD studentship (AP-2012-2901 and AP2010-2510, respectively) from the Ministerio de Educación, Cultura y Deporte of Spain. Maxi Castrillejo was also supported by the ETH Zurich Postdoctoral Fellowship Program (17-2 FEL-30), co-funded by the Marie Curie Actions for People COFUND Program. We also thank Gary Hemmings (Queens College) and Troy Rasbury (Stony Brook University) for laboratory assistance with the ICP-MS analyses. Finally, we thank the associate editor and the anonymous reviewers for their helpful comments on how to improve the manuscript.
