ABSTRACT

Accurate crop and weed discrimination plays a critical role in addressing the challenges of weed management in agriculture. The use of herbicides is currently the most common approach to weed control. However, herbicide resistant plants have long been recognised as a major concern due to the excessive use of herbicides. Effective weed detection techniques can reduce the cost of weed management and improve crop quality and yield. A computationally efficient and robust plant classification algorithm is developed and applied to the classification of three crops: Brassica napus (canola), Zea mays (maize/corn), and radish. The developed algorithm is based on the combination of Local Binary Pattern (LBP) operators, for the extraction of crop leaf textural features and Support vector machine (SVM) method, for multiclass plant classification. This paper presents the first investigation of the accuracy of the combined LBP algorithms, trained using a large dataset of canola, radish and barley leaf images captured by a testing facility under simulated field conditions. The dataset has four subclasses, background, canola, corn, and radish, with 24,000 images used for training and 6000 images, for validation. The dataset is referred herein as “bccr-segset” and published online. In each subclass, plant images are collected at four crop growth stages. Experimentally, the algorithm demonstrates plant classification accuracy as high as 91.85%, for the four classes.

1. Introduction

Weed infestation has always been a critical issue that limits the productivity of farms and the yield of crops. The ability to accurately discriminate weeds from crops in real-time will advance precision crop and weed management, whereby weeds in a field are prevented from competing for light water and nutrients required by the crops. Blanket herbicide spraying is currently the most common practice used for weed control. The worthwhile objective of precision weed control is to bring down the cost of weed management. To enhance the longevity of the current range of agricultural chemicals, it is important to deter the increase in herbicide resistant weeds.

Cereal crops such as wheat, rice, maize (corn), oats, barley, rye and sorghum, represent a large portion of the crops grown worldwide [1]. Hence, detecting dominant weeds in cereal
crop fields and controlling them in real-time will enable effective site-specific weed management, resulting in substantial economic benefits [2]. A variety of weed detection approaches based on feature extraction have been proposed, these include shape-based analysis [3,4], colour-based analysis [5], texture-based image analysis [6,7] and spectral analysis [8–10]. However, the accuracy of the above mentioned approaches has been limited due to the complexity of the field environment, the wide variety of species and the morphological variation of plants at various growth stages.

Numerous approaches to the discrimination of crops and weeds have been reported. Over the last two decades, spectral techniques based on the calculation of the Normalised Difference Vegetation Indices (NDVIs) [11,12] have been proposed for distinguishing between plant species. However, these spectral techniques have some limitations, especially when the spectral characteristics of weeds and crops are similar over the operational wavelengths. In addition, in typical farming field conditions, the wind, shadowing, and background illumination may change the spectral features of plants, thus reducing the discrimination accuracy of NDVI-based weed sensors [13,14]. The limitations of such spectral-reflectance sensors have triggered research on the development of spatial sensors, based on the use of image processing techniques, for the classification of plant species and detection of weeds in real-time.

A variety of feature extraction operators have been proposed for detecting robust features in images, based on the Scale Invariant Feature Transform (SIFT) [15], Speeded Up Robust Features (SURF) [16], the Histogram of Oriented Gradients (HOG) [17], LBP, Gabor filters [18] to name a few. In this paper, we adopt the LBP technique for plant feature extraction for several reasons. Firstly, LBP method is very flexible and robust to monotonic grey-level transformation, illumination, scaling, viewpoint, and rotation variance [6]. Secondly, the LBP method enables image analysis in challenging real-time settings, due to computational simplicity [19]. In fact, the LBP is computationally less complex than its SIFT or SURF counterparts, exhibiting high discriminability capability [20]. Finally, the LBP has exhibited superior performance in several applications, such as face recognition [21–23], face expression analysis [24,25], texture classification [6,26,27], and motion analysis [28,29].

The optimization of LBP methods for discriminating crops and weeds has proved difficult in special scenarios [30,31]. In particular, Ahmed et al. used 400 colour images (taken at an angle of 45° with respect to the ground) in natural lighting conditions, 200 samples were of broadleaves and 200 of grass weeds [31]. From observation the number of images and the types of plants collected in the dataset is limited. Reduced accuracy was attained in the field due to the relatively small number of plant images and viewpoints, variable lighting conditions and change in plant aspect ratios for each growth stage. Furthermore, several extended LBP methods have used common and published texture databases including Outex [32], Brodatz [33], UIUC [34], UMD [35] and CUREF [36] to validate, evaluate or compare classification results [37]. However, databases for the detection and classification of plant textures have not been commonly published.

Typically, after extracting good features from plant images, the next process is to classify plant species. Previous research has mainly focused on the use of artificial neural networks (ANN) [38,39], Bayesian classifiers [40–42], k-nearest neighbour (kNN) classifiers [43], discriminant analysis [44,45] and SVM classifiers [46–49] for weed identification and discrimination. According to [50–52], SVM has been regarded as a robust technique for difficult classification tasks. This paper focuses on applying the LBP method in conjunction with SVM for plant feature extraction and classification of various plant images.

The main contributions of the work in this paper are summarized as follows:

- A large plant dataset was captured by using a Testbed with around 30,000 plant images. This large dataset contains four classes, a variety of plant images at four defined growth stages, with rotation, scale and viewpoint variance in order to evaluate the robustness and performance of the method.

- Due to the low dimensionality of the plant representation and the low tolerance to illumination changes, LBP was especially investigated with different parameters for plant detection, and combined with SVM-based classification to investigate its capability to operate in real-time.

The paper consists of four sections and is structured as follows. Section 1 explains why weed detection plays a crucial role in agricultural precision. It also introduces the selected method and presents a brief review of LBP analysis, together with the advantages and disadvantages of the proposed weed detection and classification approach. Section 2 describes the principles of the LBP technique and the rationale of combining LBP operators with SVM for the extraction of key features from plant images and the classification of different types of plants in a large dataset. Performance measures for classification, data collection, and a detailed flowchart for training and validating the dataset are also covered in Section 2. In Section 3, an initial comparison of greyscale unsegmented and segmented images used in plant discrimination is provided. Results are presented in Section 3, indicating that performance is best achieved by using segmented images (i.e. working with the green plant material extracted from images and converting it to greyscale).

Based on these initial results, the data set “bccr-segset” is collected in the form of greyscale segmented images. Then, the classification accuracy and F1 scores of groups with different plant classes are discussed in detail, illustrating the effectiveness of the methodology in regard to plant detection and classification. Finally, conclusions and future work are discussed in Section 4.

2. Materials and methods

This section describes the methodology and performance metrics that lead to the generation of the results shown in Section 3. The theoretical concept and principle of the selected methods in segmentation, feature extraction and
classification processes are detailed in Sections 2.1–2.3. Classification accuracy and F1 scores measures are presented in Section 2.4. Data collection is explained in detail in Section 2.5.

2.1. Segmentation

Image segmentation refers to the process of partitioning an image into multiple segments or regions. In terms of weed detection, this process is based on the segmentation of green plant material (crops and weeds) and non-green background areas (i.e. soil and residues). Removing the background areas of the images enables better plant feature extraction and classification.

In this paper, the ExG-ExR (Excess Green minus Excess Red Indices) method is used to segment green plant regions. This colour index-based method has exhibited adequate robustness and high accuracy compared to other methods, such as ExG (Excess Green Index)+Otsu and NDI (Normalised Difference vegetation Index)+Otsu under greenhouse field lighting conditions and natural field lighting conditions [53]. Typically, the ExG component extracts green information, while the ExR component eliminates the background noise [54]. An example of image segmentation is illustrated in Fig. 1, which shows canola, corn and radish plants that were randomly arranged along the testing trays of a test bed. The vegetation indices of the RGB plant image were first extracted by applying the ExG-ExR approach, then, the image was converted to a greyscale image before applying feature extraction and classification.

2.2. Local binary pattern operators

To better understand how LBP is applied for weed detection, a brief background on LBP is presented. The LBP method has been regarded as a powerful tool for extracting robust features from texture-based image analysis and classifying objects based on local image texture properties. The first LBP algorithm was reported in 1996 [55], since then, various LBP algorithms have been developed to primarily detect textures or objects in images. A very small local neighbourhood of a pixel is used to calculate a feature vector. Basically, the LBP operator labels the pixels of an image by thresholding the local structure around each pixel and considering the result as a binary number. Fig. 2 illustrates an example of computing LBP in a 3 x 3 neighbourhood by comparing the intensities of the eight neighbours around each pixel with the intensity of the centre pixel. When the intensity of the centre pixel is greater than that of a neighbour, it is considered to be ‘0’, otherwise ‘1’. A binary chain is obtained by combining every single binary code in a clockwise direction. For Fig. 2, the binary code is 11110001, or 241 in decimal [55]. The binary number is used to build a histogram, which can be regarded as representing the texture of an image.

The main limitation of the LBP operator presented above is that it only covers a small area of the neighbourhood. For a small 3 x 3 neighbourhood the LBP fails to capture dominant textural features in an image. As a result, the LBP operator was improved upon by increasing the number of pixels and the radius in the circular neighbourhood [6]. Note that it is typically more flexible and effective to improve LBP operators.

Fig. 1 – Images of canola, corn and radish: (a) full RGB image, (b) image with extracted green material (plants), and (c) greyscale image of (b).
using textures of different scales. Generally, the value of the LBP code of a pixel \((x_c, y_c)\) can be calculated as follows [6]:

\[
\text{LBP}_{p,r} = \sum_{p=0}^{R} s(g_p - g_c)2^p \quad \text{where} \quad s(x) = \begin{cases} 1, & x \geq 0 \\ 0, & x < 0 \end{cases}
\]  

(1)

where

\(g_c\): is the grey value of the centre pixel.

\(g_p\): represent the grey values of the circularly symmetric neighbourhood from \(p = 0\) to \(P - 1\) and \(g_p = x_{p,r}\).

\(P\): is the number of surrounding pixels in the circular neighbourhood with the radius \(R\).

\(s(x)\): is the thresholding step function which helps the LBP algorithm to gain illumination invariance against any monotonic transformation.

According to Eq. (1), the \(\text{LBP}_{p,r}\) operator produces \(2^P\) different output values. If the image is rotated, the grey values, \(g_p\), of the circularly symmetric neighbourhood will move correspondingly along the perimeter of the circle. This generates a different LBP value, except for patterns with only the value ‘0’ or ‘1’. In order to eliminate rotation effects, a rotation-invariant LBP is defined as follows [6]:

\[
\text{LBP}^{\text{ri}}_{p,r} = \min\{\text{ROR}(\text{LBP}_{p,r}, i) \mid i = 0, 1, \ldots, P - 1\}
\]  

(2)

where \(\text{ROR}(x, i)\) performs an i-step circular bit-wise right shift on the P-bit number \(x\).

To choose good and quality features, feature space dimensionality needs to be reduced by keeping only the rotationally-unique patterns. Accordingly, Ojala et al. named these patterns uniform patterns. The patterns denoted as \(\text{LBP}^{\text{ui}}_{p,r}\) stand for the number of spatial transitions in the patterns meaning that the uniform patterns need to have two bitwise transitions from 0 to 1 or vice versa. For instance, uniform patterns with eight pixels in the circular neighbourhood, 00000000 (0 transitions), 11111111 (0 transitions), or 01110000 (2 transitions) are uniform because the parameter \(U\) that measures the uniformity has at most 2 transitions. Examples of non-uniform patterns are: 00000101 (4 transitions) and 01000101 (6 transitions). Consequently the rotation invariant uniform descriptor \(\text{LBP}^{\text{ui}}_{p,r}\) can be defined as follows [6]:

\[
\text{LBP}^{\text{ui}}_{p,r} = \sum_{p=0}^{P} s(x_{p,r} - x_c), \quad \text{if} \ U(\text{LBP}_{p,r}) \leq 2 \\
\frac{P+1}{2}, \quad \text{if} \ U(\text{LBP}_{p,r}) > 2
\]  

(3)

The uniform descriptor has \(P(P - 1) + 3\) patterns including \(P(P - 1) + 2\) distinct uniform patterns and all non-uniform patterns assigned to a group \(P + 1\). According to Ojala et al., the rotation invariant uniform descriptor has \((P + 2)\) distinct output patterns [6]. This reduces the feature space and helps increase the speed of LBP. For example, if the number of pixels in the circular neighbourhood is 8, the number of uniform patterns is 58 and the number of rotation invariant uniform patterns is 10.

2.3. Support vector machine

The final stage in the image processing is classification. There are different machine learning methods such as decision trees, SVM, neural networks, k-nearest neighbour method, and the Bayesian classifier. For a classifier to achieve good performance, sufficient data needs to be acquired and the training performance analysed. The SVM can deal with pattern classification and eliminate over-fitting, and it is robust to noise [47,56]. SVM was first introduced in 1992 [57]. SVM performs classification more accurately than other algorithms in many applications, especially those applications involving very high dimensional data [42,46,47,58,59]. This high performance makes the SVM classifier a preferred option for many applications, such as face recognition, weed identification and disease detection in plant leaves. Therefore, the optimal combination of the LBP descriptors and SVM classification can result in high plant discrimination accuracy. In particular, SVM generates an optimal hyper-plane that maximizes the margin between the classes.

To be a good discriminative classifier, SVM needs to use an appropriate kernel function. Due to the separation of the learning algorithm and kernel functions, kernels can be studied independently of the learning algorithm. One can design and experiment with different kernel functions without...
touching the underlying learning algorithm. Commonly, polynomial or Gaussian RBF (Radial Basis Function) kernels are used in most applications, depending on the types of data. In this paper, 2nd order polynomials and 5-fold cross validation are used. Specifically, the training set is firstly divided into five subsets of equal size, and four parts of the data are iteratively used for training, with the remaining part of data used for testing. This cross-validation procedure helps to prevent data overfitting and subsequent loss of generalization.

2.4. Performance metrics for plant classification

The common way of assessing a classification algorithm is to calculate its classification accuracy, which is defined as:

\[
\text{Classification Accuracy} \%
= \frac{\text{Number of correct classifications}}{\text{Total number of samples}} \times 100\%
\]

However, in order to assess the performance of the SVM classifier for each class, confusion matrices are evaluated by computing main metrics, namely: precision, recall and F1 score, from the measured true positives, false positives, true negatives and false negatives. This method has been applied in many studies to evaluate the performance of classification models [60–62]. All parameters differentiate the correct classification of labels within different classes [63,64]. A basic confusion matrix comprises 4 entries: True Positive (TP), False Negative (FN), False Positive (FP) and True Negative (TN). According to [64], we can calculate the average of precision, recall and F1 score for multi-class classification by firstly computing these parameters based on TP, TN, FN, and FP in each class as follows:

\[
\text{Recall} (\text{class}) = \frac{TP(\text{class})}{TF(\text{class}) + FN(\text{class})}
\]

\[
\text{Precision} (\text{class}) = \frac{TP(\text{class})}{TF(\text{class}) + FP(\text{class})}
\]

\[
F1\text{score} (\text{class}) = \frac{2 \times \text{Precision}(\text{class}) \times \text{Recall}(\text{class})}{\text{Precision}(\text{class}) + \text{Recall}(\text{class})}
= \frac{2TP(\text{class})}{2TP(\text{class}) + FN(\text{class}) + FP(\text{class})}
\]

Precision in each class is defined as the number of correctly classified positive plant images divided by the total number of plant images in the data. Recall in each class is the ratio of the number of correctly classified positive plant images to the number of positive plant images in the data. F1 score in each class is a composite measure of precision and recall in each class.

2.5. Data collection

In this study all the data was captured on a custom-built testing facility at ESRI (Electron Science Research Institute), Edith Cowan University, Australia, which is shown in Figs. 3 and 4. The hardware comprises a Xilinx Zynq ZC702 development platform [65] that captures HD images (1920 × 1080 pixels) at 60 frames per second using an On-Semi VITA 2000 camera sensor. The Zynq development board and camera are mounted on a moveable trolley with the camera optical axis perpendicular to the ground and move on a linear drive across the frame of the Testbed. The captured images have a spatial resolution of ~1mm/pixel and a size of 228 × 228 pixels. In addition, the vertical height of the camera above the surface of the plant pots is 980 mm and 9 mm is the camera focal length.

As can be seen in Fig. 3, individual trays are capable of holding 11 potted plants, with each tray filled with soil to provide a uniform background that can be used to simulate a West Australian wheat belt farming environment. For experimental purposes, only the outer pot plant holders of the middle tray were used.

The maximum allowable speed of the trolley is 5 m/s, with the system capable of capturing images in real-time. The Testbed is also equipped with two fluorescent tube lamps as
illustrated in Fig. 3. The artificial lighting is there to provide uniform illumination for the purposes of data capture. For the purposes of the experimental work presented herein, all data was captured at a speed of 1 m/s (3.6 km/h) to capture high quality images.

Data capture runs comprised collecting multiple images of the individual test plants placed in the centre Testbed tray, Fig. 3, with image variation obtained through manual plant rotation. The segmented greyscale images collectively formed the large data set used in the experimental work. This data set is referred to herein as "bccr-segset" and published online.

2.5.1. Data labelling
Data labelling was conducted by providing the ground truth in regard to which types of plants were identified in images. In the context of continuous runs on the Testbed, images comprised just background, partial plant with background or full plant with background, making the detection and classification processes challenging. Whilst the partial plant images could be removed from the dataset altogether, this would introduce a dataset bias. On the other hand, the human labelling error was quite high when attempts were made to decide among the labels that contained little plant information (i.e. "is this background or plant?"). Therefore, a semi-automatic way was adopted to solve this problem by thresholding the amount of green plant material according to their growth stages. If an image did not contain enough green plant material, then it was labelled as background.

First of all, as a pre-processing stage, images were filtered by using open and close morphological operations in order to remove the background noise. Then, binary images were segmented and thresholded according to the amount of corresponding plant area found. Initial experiments showed that it was not sufficient to do a green threshold on the entire image, therefore images were divided into 7 equal areas (Top left, Top right, Bottom left and Bottom Right, Centre left, Centre and Centre right) as shown in Fig. 5.

The thresholding test was applied for each of the square areas shown in Fig. 5. The image was labelled as a plant class if the thresholding test passed for any of the areas. Lastly, an edge area threshold was also defined in order to allow for partial plants to have enough green material for identification. All the thresholds were experimentally derived and are shown in Table 1.

As can be seen in Fig. 6, partial plants in some growth stages with insufficient information were considered as a background class in the dataset. This allowed a more reliable labelling process without removing images from the dataset. In turn, this assured that the input sample distribution did not change.

2.6. Methodology
All of the plant images went through the following processing steps: pre-processing, segmentation, feature extraction and classification. The extracted LBP features were stored in a database. Pre-processing was the same for both training and
validation phases. The training dataset was trained by using the SVM and then the prediction model was exported to compare with textural features in the validation set for recognising and classifying different types of plants.

Steps in the process of the training, testing and validation of the dataset through the combination of LBP operators and SVM for three-plant classification are summarised as follows:

1. The dataset with greyscale segmented images is provided to start the process.
2. To read all plant images, the location of the dataset is input.
3. The dataset is divided into the training and validation phases.
4. The LBP hyper-parameters are set, including the number of neighbours (P) and the radius (R), and a rotation invariant uniform (riu2) descriptor. In the preliminary results, $LBP_{riu2}^{8,1} + LBP_{riu2}^{16,2} + LBP_{riu2}^{24,3}$ and combined LBP operators $\left( LBP_{riu2}^{8,1} + LBP_{riu2}^{16,2} + LBP_{riu2}^{24,3} \right)$ are applied to extract robust features from plant images.
5. The LBP method is initialised by inputting hyper-parameters then run to extract features from plant images.
6. Canola, Corn, Radish and Background are labelled by using the Testbed system in the data collection stage. For this step, a table of features and labels is generated to input into Matlab to train the dataset by using the LBP algorithm and SVM classifier.
7. The table of robust features and labels is regarded as an input dataset for training.
8. Apply the SVM approach with 5-fold cross validation to classify different types of plants. After training the dataset, a model is exported to make predictions for the plant images in a validation dataset.

3. Results and discussion

The results are divided into two sections: (i) the accuracies of classification models are evaluated based on comparing an unsegmented validation dataset with a validation segmented dataset, and (ii) the classification accuracy of the LBP operators and the SVM in the large dataset is reported. As noted in the data collection section, plant images were captured at the same height from the camera to the plant pots. Therefore, the scales of the images of the plants taken during the four growth stages corresponded to the actual sizes of the plants. The computer used in these experiments had a 3.4 GHz processor, 16 GB RAM and ran MATLAB 2016b.

3.1. Initial results of the comparison between classification accuracies of an unsegmented dataset and a segmented dataset

In this section, an initial performance comparison is made between segmented and unsegmented greyscale images. With regard the current experimental setup, the effort required to capture and label the unsegmented greyscale images is greater than that of capturing segmented images. Experiments are conducted by selecting unsegmented and segmented datasets with 4032 images in each dataset. The detailed parameters of the two datasets are listed in Table 2.

The results of the classification accuracy were assessed against the percentages of correct classified plants. It can be observed from Table 3 that the combination of LBP operators significantly improves the classification accuracies in the validation sets. According to Ojala et al., the performance of the combined LBP operators outperformed that of single LBP operators [6]. In this experiment, it was obviously true that the classification accuracies achieved using the combination of \( LBP_{8,1}^{2}, LBP_{16,1}^{2} \) and \( LBP_{24,3}^{2} \) was also higher than those attained using single LBP operators. This demonstrates that robust features extracted through the combined-LBP operators can increase the classification accuracy and F1 scores. In comparison with using the greyscale unsegmented dataset, the accuracy of classification models using the validation segmented dataset is generally higher.

The experimental results shown in Table 3 show that converting RGB plant images into greyscale without segmentation does not increase the classification accuracy. Whereas, by segmenting RGB images using the ExG-ExR method and then converting them to greyscale results in higher classification accuracy. Furthermore, experimental results show that by applying the above-mentioned pre-segmentation steps an increase of 2–4% in accuracy is attained, for the detection and discrimination of plant species.

Principal Component Analysis (PCA) is a useful tool for reducing the dimensionality of data. Typically, PCA produces the principal components of an image and extracts the relevant features from the data matrix of the image by calculating the eigenvalues. Note, however, in some cases, many significant features could be eliminated when PCA is applied, thereby reducing plant discrimination accuracy [66,67]. Therefore, optimising the number of retained principal components is important for increasing plant discrimination accuracy. In our experiments, PCA was used in conjunction with the combined-LBP operators and SVM, and the optimum number of principal components for our algorithms was

found to be 16. This optimum number was deduced experimentally and is offered herein for completion. Note that classification accuracy is not a sufficient indicator to claim that the model is acceptable for plant classification \[63\]. In fact, three other indicators (Precision, Recall, and F1 score) are typical to validate the suitability of the model for plant classification. Table 4 shows the F1 scores of the classification models for the validation unsegmented and validation segmented datasets, for canola and corn plants. As seen from Table 4, the F1 scores for canola and corn plants are relatively similar. It is obvious from Table 4 that the highest F1 scores (>99%) are attained with segmented data and the combination of \(LBP_{8,1}\) and \(LBP_{24,3}\).

### 3.2. Classification accuracies and F1 scores of a multi-class dataset

Having investigated the performance of the greyscale segmented images (in Section 3.1), we discuss in this section the performance of the method based on the combination of the LBP operators and SVM for a larger dataset, using only greyscale segmented images.

In these experiments canola, corn and radish plants were collected at four different growth stages, Fig. 8, using the custom-built testbed. Images were segmented and converted to greyscale with the size of \(228 \times 228\) pixels. The datasets were divided into training and validation, as illustrated in Fig. 9.

The training dataset was used to train the SVM classifier with 5-fold cross validation to generate a prediction model for the validation dataset. Kernel functions were introduced to enhance efficient non-linear classification. Note that polynomial kernels and radial basis functions are widely used with SVM \[68\]. Different kernels were trialled in the experiments with the quadratic kernel was found to be more effective for SVM and LBP combination, the quadratic kernel generating the best and most consistent results. The “one against one” SVM strategy was selected in this scenario due to the large number of training images \[69\]. This obtained the optimum compromise between training time and accuracy performance. MATLAB was used to visualize the distribution of the LBP textural features.

Fig. 10 shows the distribution of the training dataset for canola, corn, radish and background, using LBP operators \(LBP_{8,1}\) and \(LBP_{24,3}\). The scatter plot shown in Fig. 10 illustrates the distribution of two selected features out of a total of 54 features. From the plant images, it is obvious that the texture of the corn leaves is completely different to that of the leaves of canola and radish. Corn is categorised as a narrow leaf plant, whilst canola and radish are broad leaf plants. The distributions of canola and radish plant features overlap, mainly because their measured textural features are similar, making their discrimination challenging. Intuitively, these plants have the same botanical family (Brassicaceae or Cruciferae) and corn belongs to grass family (Poaceae). However, this plot is limited by the distribution of 2 selected features.

In order to visualize the structure of the “bccr-segset” large dataset in a two-dimensional map, we used t-SNE technique \[70\] for the train dataset (24,000 plant images) and test dataset (6000 plant images). According to \[70\], as well as the user’s guide for t-SNE, we implemented this technique in Matlab,

and used the main parameters, such as two-dimensional visualization, dimensionality reduction of the data (the value was 50), perplexity of the Gaussian distributions (the value was 30). Fig. 11 shows (a) the train dataset (24000 plant images) and (b) the test dataset (6000 plant images) with 4 classes (background, canola, corn and radish). As can be seen from Fig. 11, the distribution of background class is totally separated from other classes. Meanwhile, the distributions of corn, canola and radish images were classified into many small groups and had some overlapping patterns, leading to higher misclassification rates among canola, corn and radish images.

For the validation set, the generated prediction model was applied to evaluate the robustness of this model by evaluating the classification accuracies for scenarios of two classes, three classes and four classes. To evaluate the quality of classification of the model, we applied performance measures to calculate the confusion matrices described in Section 2.4.

Performance metrics for multi-class classification were computed by applying the general formulas from Sokolova and Lapalme [64]. After training the 24000-plant-image dataset, Table 5 shows the average classification accuracy results obtained on the test dataset (6000 plant images) by using the combination LBP operators $LBP_{16}^{24}$, $LBP_{16}^{24}$, $LBP_{16}^{24}$ with PCA (16 principle components) and without PCA. The classification accuracy of LBP operators without PCA shown in Table 5 was relatively higher than the one with PCA. However, a slight improvement in execution time was obtained by applying PCA, due to reduction of features considered to 16 dominant features.

To have a better understanding of classification for classes, Table 6 shows the confusion matrix of the test dataset for four classes which was obtained by using SVM (polynomial kernel, order 2) without PCA. After calculating the number of correctly and falsely classified images in the confusion matrix,
TP, FP and FN parameters in each class were calculated. We applied performance measures to calculate the confusion matrix, precision, recall and F1-score of the test dataset described in Section 2.4 by using the SVM classifier (polynomial kernel, order 2) were computed as shown in Table 7.

The evaluation of the performance of different SVM kernels is presented in Table 7. According to a comparison of the F1 scores for multi-class classification, the classification performance of SVM (polynomial kernel, order 2, box constraint level: 1) with 91.83% was higher than SVM (polynomial kernel, order 3, box constraint level: 1) and SVM (RBF kernel, box constraint level: 1, and kernel scale: $\sqrt{\text{(number of features)}}$) with 90.66% and 90.78% respectively. Furthermore, corn and background classes were classified with high accuracy. In contrast, for groups with many similar features (canola and radish), the algorithm displayed reduced discrimination capability.

The distinctions in the leaf texture of plants and the number of green pixels in images provided significant information for the reliability of classification results. In particular, the differences between narrow-leaf and broadleaf plants enhanced the classification rates. Therefore, background and corn images were classified with higher accuracy compared to canola and radish images. As for the similarity between canola and radish plants, the F1 scores of differentiating between them in Table 7 were considerably lower. These plants with round shaped leaves can be discriminated by simply recognizing the edges of canola plants, which generally look like outward-pointing teeth. In addition, one of the main obstacles for the relatively high misclassification rates is that

\caption{Classification accuracies of an algorithm combining LBP operators ($LBP_{8,1}^{(16),2}$, $LBP_{16,2}^{(24),2}$, $LBP_{24,3}^{(24),3}$) and SVM for different scenarios. Execution time and PCA is shown herein for completion.}
\end{table}
plant leaves may look unexpectedly deformed and twisted after imaging, since these plants are not always perpendicular to the camera lens. Overall, the algorithm combining LBP operators with SVM produced consistently robust classification, scale and rotation invariance.

To investigate the performance of SVM kernels, we conducted a comparative study of the F1 scores for SVM classifier and K-Nearest Neighbour (KNN) classifier. KNN is an algorithm for classifying classes based on a similarity measure (distance functions) [71]. This method has two types of distance functions including distance metric and distance weight [72]. Particularly, three distance metrics including Euclidean, Minkowski and Cosine were used in this experiment and the results were computed by using Matlab. Table 8 shows the Precision, Recall and F1-score in the case of three different SVM kernels. As can be observed in Table 8, the F1 score at stage 1 was higher than those at other stages. The morphology of canola and radish in stage 1 is distinctly different. Specifically, the two-heart shape of radish leaves in stage 1 has a distinctive appearance compared to the shape of canola leaves. As for the stage 2 and 3, the classification performance of SVM (RBF kernel) was higher than of SVM (polynomial kernel, order 2 and 3). However, the number of correctly classified plant images based on the F1 score was higher for the SVM (polynomial kernel, order 2) in comparison with the SVM (RBF kernel).

The capability of discriminating between canola and radish images in Table 9 was always lower than for background and corn images. Consequently, improving the LBP method is crucial to discriminate plant species with relatively similar features. A possible way to achieve this is to combine the uniform rotation invariant LBP features with significant non-uniform LBP features. Another potential approach is to take...

all features of the LBP method to acquire vital information of microscopic images of the plant species [73]. These are promising approaches that enable the development of LBP algorithms for the discrimination of plant species of similar features.

4. Conclusions & future work

An algorithm based on the combination of LBP operators and an SVM classifier has been investigated, and its performance experimentally evaluated for the discrimination of different types of plants. An initial comparison of unsegmented and segmented dataset types has been carried out in order to identify the type that yields higher classification accuracy. This comparison has shown that the green segmentation pre-processing step is beneficial for feature extraction and classification. A large segmented dataset has been collected using a high-speed Testbed that enabled the methods to be assessed and validated. A dataset has been made available (published online), which can be flexibly used by other researchers for information and comparison. Particularly, eight cases have been created using the large dataset and the experimental results have demonstrated that the combined LBP algorithm can attain a discrimination accuracy greater than 91% for corn, canola and radish plants and background. Results have also shown that if the shapes of canola and radish leaves are similar, the classification accuracy of the LBP algorithm decreases significantly. Furthermore, results have shown that the current execution time of plant classification is short, making the combined LBP algorithm a promising candidate for real-time weed detection.

Future work is focusing on the extension of the LBP method using colour images (instead of grey-level) and the introduction of identification techniques based on the use of non-uniform patterns in order to increase the weed detection accuracy. In addition, further investigations are required for improving the classification of broad leaves (e.g., radish and canola) and assessing the LBP algorithm in scenarios in which weeds and crops are partially occluded.

Conflict of interest

The authors declared that there is no conflict of interest.

Acknowledgments

The research was funded by Grains Research and Development Corporation (GRDC) and the authors would like to thank the Pawsey Supercomputing Centre for storing the large dataset.
